We show that atoms trapped in micro-cavities that interact via exchange of virtual photons can model an anisotropic Heisenberg spin-1/2 chain in an external magnetic field. All parameters of the effective Hamiltonian can individually be tuned via external lasers. Since the occupation of excited atomic levels and photonic states are strongly suppressed, the effective model is robust against decoherence mechanisms, has a long lifetime and its implementation is feasible with current experimental technology. The model provides a feasible way to create cluster states in these devices.

Introduction: Interacting two level systems, either termed spins or qubits, are of central importance in quantum information and condensed matter physics. Two or higher dimensional magnetic compounds are believed to host some of most interesting condensed matter phenomena, such as frustration and high T_c superconductivity [1], which are not yet fully understood. In quantum information, lattices of interacting spins can be employed to generate highly entangled states, such as cluster states which are the required resource for one way quantum computation [2]. While it is a prerequisite for quantum information processing, the ability to address individual spins in an experimental device can also be very helpful to obtain deeper and more detailed insight into condensed matter physics.

In magnetic compounds where spin lattices appear naturally the addressability of individual spins is unfortunately extremely hard to achieve because the spatial separation between neighboring spins is very small and the timescales of interesting processes can be very short.

Here we show that effective spin lattices [3] can be generated with individual atoms in micro-cavities that are coupled to each other via the exchange of virtual photons. Due to the size and separation of the micro-cavities, individual lattice sites can be addressed with optical lasers, whereas the cavities can be arranged arbitrarily allowing for various lattice geometries. The two spin polarizations $|\uparrow\rangle$ and $|\downarrow\rangle$ are thereby represented by two longlived atomic levels of a Λ level-structure (c.f. figures 1 and 2). Together with external lasers, the cavity mode that couples to these atoms can induce Raman transitions between these two long-lived levels. Due to a detuning between laser and cavity mode, these transitions can only create virtual photons in the cavity mode which mediate an interaction with another atom in a neighboring cavity. With appropriately chosen detunings, both the excited atomic levels and photon states have vanishing occupation and can be eliminated from the description. As a result, the dynamics is confined to only two states per atom, the long-lived levels, and can be described by a spin-1/2 Hamiltonian. Due to the small occupation of photon states and excited atomic levels, spontaneous emission and cavity decay are strongly suppressed. All these results are verified by detailed numerics. A realization of the scheme thus requires cavities that operate in a strong coupling regime with a high cooperativity factor and an atom photon coupling that exceeds cavity decay. Such regimes have now been achieved in several devices [4, 5, 6], making a realization of the presented scheme feasible with current technology. We begin by showing how to engineer effective $\sigma^x\sigma^x$, $\sigma^y\sigma^y$ and $\sigma^z\sigma^z$ interactions as well as the effective magnetic field σ_z and then explain how to generate the full anisotropic Heisenberg model. We verify the validity of all approximations by comparison with the exact dynamics of the full atom-cavity model and also apply the model to the generation of cluster states. Finally we discuss the feasibility of our model for realistic experimental parameters.

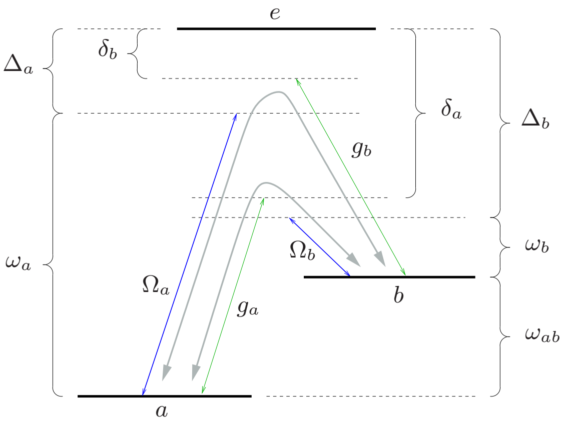

FIG. 1: Level structure, driving lasers and relevant couplings to the cavity mode to generate effective $\sigma^x\sigma^x$- and $\sigma^y\sigma^y$-couplings for one atom. The cavity mode couples with strengths g_a and g_b to transitions $|a\rangle \leftrightarrow |e\rangle$ and $|b\rangle \leftrightarrow |e\rangle$ respectively. One laser with frequency ω_a couples to transition $|a\rangle \leftrightarrow |e\rangle$ with Rabi frequency Ω_a and another laser with frequency ω_b to $|a\rangle \leftrightarrow |e\rangle$ with Ω_b. The dominant 2-photon processes are indicated in faint gray arrows.

XX and YY interactions: We consider an array of cavities that are coupled via exchange of photons with one 3-level atom in each cavity (figure 1). Two long lived levels, $|a\rangle$ and $|b\rangle$, represent the two spin states. The cavity mode couples to the transitions $|a\rangle \leftrightarrow |e\rangle$ and $|b\rangle \leftrightarrow |e\rangle$, where $|e\rangle$ is the excited state of the atom. Furthermore, two driving lasers couple to the transitions $|a\rangle \leftrightarrow |e\rangle$ respectively $|b\rangle \leftrightarrow |e\rangle$. The Hamiltonian of the atoms reads $H_A = \sum_{j=1}^{N} \omega_e |e_j\rangle\langle e_j| + \omega_{ab}|b_j\rangle\langle b_j|$, where the index j counts the cavities, ω_e is the energy of the excited level and ω_{ab} the energy of level $|b\rangle$. The energy of level $|a\rangle$ is set to zero and we use $\hbar = 1$. The Hamiltonian that describes the photons in the cavity modes is $H_C = \omega_C \sum_{j=1}^{N} a_j^\dagger a_j + J_C \sum_{j=1}^{N} \left(a_j^\dagger a_{j+1} + a_j a_{j+1}^\dagger \right)$, where $a_j^\dagger$ creates a photon in cavity j, ω_C is the energy of the photons and J_C the tunneling rate of photons between neighboring cavities [7]. For convenience we assume periodic boundary conditions, where H_C can be diagonalized via the Fourier transform $a_k = \frac{1}{\sqrt{N}} \sum_{j=1}^{N} \mathrm{e}^{\mathrm{i}kj} a_j$; $k = \frac{2\pi l}{N}$; $-\frac{N}{2} \le l \le \frac{N}{2}$ (N odd) to give $H_C = \sum_k \omega_k a_k^\dagger a_k$ with $\omega_k = \omega_C + 2J_C \cos(k)$. Finally the interaction between the atoms and the photons as well as the driving by the lasers are described by $H_{AC} = \sum_{j=1}^{N} \left[\left(\frac{1}{2}\Omega_a \mathrm{e}^{-\mathrm{i}\omega_a t} + g_a a_j \right) |e_j\rangle\langle a_j| + \mathrm{h.c.} \right] + +[a \leftrightarrow b]$. Here g_a and g_b are the couplings of the respective transitions to the cavity mode, Ω_a is the Rabi frequency of one laser with frequency ω_a and Ω_b the Rabi frequency of a second laser with frequency ω_b [8]. The complete Hamiltonian is then given by $H = H_A + H_C + H_{AC}$.

We now switch to an interaction picture with respect to $H_0 = H_A + H_C - \delta_1 \sum_{j=1}^{N} |b_j\rangle\langle b_j|$, where $\delta_1 = \omega_{ab} - (\omega_a - \omega_b)/2$, and adiabatically eliminate the excited atom levels $|e_j\rangle$ and the photons [9]. We consider terms up to 2nd order in the effective Hamiltonian and drop fast oscillating terms. For this approach the detunings $\Delta_a \equiv \omega_e - \omega_a$, $\Delta_b \equiv \omega_e - \omega_b - (\omega_{ab} - \delta_1)$, $\delta_a^k \equiv \omega_e - \omega_k$ and $\delta_b^k \equiv \omega_e - \omega_k - (\omega_{ab} - \delta_1)$ have to be large compared to the couplings Ω_a, Ω_b, g_a and g_b, i.e. $|\Delta_a|, |\Delta_b|, |\delta_a^k|, |\delta_b^k| \gg |\Omega_a|, |\Omega_b|, |g_a|, |g_b|$ (for all k). Furthermore, the parameters must be such that the dominant Raman transitions between levels a and b are those that involve one laser photon and one cavity photon each (c.f. figure 1). To avoid excitations of real photons via these transitions, we furthermore require $\left|\Delta_a - \delta_b^k\right|, \left|\Delta_b - \delta_a^k\right| \gg \left|\frac{\Omega_a g_b}{2\Delta_a}\right|, \left|\frac{\Omega_b g_a}{2\Delta_b}\right|$ (for all k).

Hence whenever the atom emits or absorbs a virtual photon into or from the cavity mode, it does a transition from level $|a\rangle$ to $|b\rangle$ or vice versa. If one atom emits a virtual photon in such a process that is absorbed by a neighboring atom, which then also does a transition between $|a\rangle$ to $|b\rangle$, an effective spin-spin interaction has happened. Dropping irrelevant constants, the resulting effective Hamiltonian reads

$$H_{\mathrm{xy}} = \sum_{j=1}^{N} B\sigma_j^z + \left(J_1 \sigma_j^+ \sigma_{j+1}^- + J_2 \sigma_j^- \sigma_{j+1}^- + \mathrm{h.c.} \right),$$

where $\sigma_j^z = |b_j\rangle\langle b_j| - |a_j\rangle\langle a_j|$ and $\sigma_j^+ = |b_j\rangle\langle a_j|$. The parameters B, J_1 and J_2 are given to second order by [10]. If $J_2^\star = J_2$, this Hamiltonian reduces to the XY model,

$$H_{\mathrm{xy}} = \sum_{j=1}^{N} B\sigma_j^z + J_x \sigma_j^x \sigma_{j+1}^x + J_y \sigma_j^y \sigma_{j+1}^y , \qquad (1)$$

with $J_x = (J_1 + J_2)/2$ and $J_y = (J_1 - J_2)/2$.

For $\Omega_a = \pm(\Delta_a g_a / \Delta_b g_b)\Omega_b$ with Ω_a and Ω_b real, the interaction is either purely $\sigma^x\sigma^x$ $(+)$ or purely $\sigma^y\sigma^y$ $(-)$ and the Hamiltonian (1) becomes the Ising model in a transverse field, whereas the isotropic XY model ($J_x = J_y$) [11] is obtained for either $\Omega_a \to 0$ or $\Omega_b \to 0$. The effective magnetic field B in turn can, independently of J_x and J_y, be tuned to assume any value between $|B| \gg |J_x|, |J_y|$ and $|B| \ll |J_x|, |J_y|$ by varying δ_1. Thus we will be able to drive the system through a quantum phase transition. Now we proceed to show how to engineer effective ZZ interactions.

ZZ interactions: To obtain an effective $\sigma^z\sigma^z$ interaction, we again use the same atomic level configuration but now only one laser with frequency ω mediates atom-atom coupling via virtual photons. A second laser with frequency ν is used to tune the effective magnetic field via a Stark shift. The atoms together with their couplings to cavity mode and lasers are shown in figure 2. The Hamiltonians H_A of the atoms and H_C of the cavity modes thus

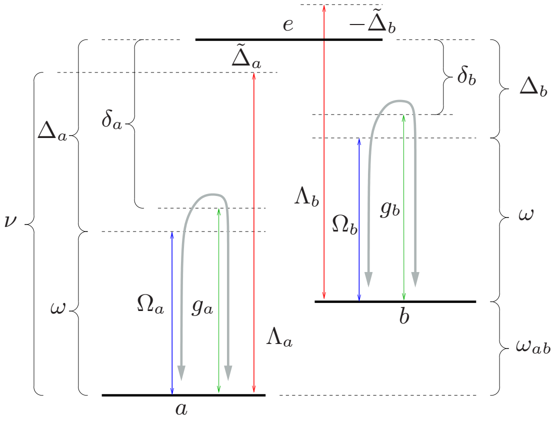

FIG. 2: Level structure, driving lasers and relevant couplings to the cavity mode to generate effective $\sigma^z\sigma^z$-couplings for one atom. The cavity mode couples with strengths g_a and g_b to transitions $|a\rangle \leftrightarrow |e\rangle$ and $|b\rangle \leftrightarrow |e\rangle$ respectively. Two lasers with frequencies ω and ν couple with Rabi frequencies Ω_a respectively Λ_a to transition $|a\rangle \leftrightarrow |e\rangle$ and Ω_b respectively Λ_b to $|b\rangle \leftrightarrow |e\rangle$. The dominant 2-photon processes are indicated in faint gray arrows.

have the same form as above, whereas H_{AC} now reads: $H_{AC} = \sum_{j=1}^{N} \left[\left(\frac{\Omega_a}{2} \mathrm{e}^{-\mathrm{i}\omega t} + \frac{\Lambda_a}{2} \mathrm{e}^{-\mathrm{i}\nu t} + g_a a_j \right) |e_j\rangle\langle a_j| + \mathrm{h.c.} \right] + [a \leftrightarrow b]$. Here, Ω_a and Ω_b are the Rabi frequencies of the driving laser with frequency ω on transitions $|a\rangle \rightarrow |e\rangle$ and $|b\rangle \rightarrow |e\rangle$, whereas Λ_a and Λ_b are the Rabi frequencies of the driving laser with frequency ν on transitions $|a\rangle \rightarrow |e\rangle$ and $|b\rangle \rightarrow |e\rangle$.

We switch to an interaction picture with respect to $H_0 = H_A + H_C$ and adiabatically eliminate the excited atom levels $|e_j\rangle$ and the photons [9]. Again, the detunings $\Delta_a \equiv \omega_e - \omega$, $\Delta_b \equiv \omega_e - \omega - \omega_{ab}$, $\tilde{\Delta}_a \equiv \omega_e - \nu$, $\tilde{\Delta}_b \equiv \omega_e - \nu - \omega_{ab}$, $\delta_a^k \equiv \omega_e - \omega_k$ and $\delta_b^k \equiv \omega_e - \omega_k - \omega_{ab}$ have to be large compared to the couplings $\Omega_a, \Omega_b, \Lambda_a, \Lambda_b, g_a$ and g_b, i.e. $|\Delta_a|, |\Delta_b|, |\delta_a^k|, |\delta_b^k| \gg |\Omega_a|, |\Omega_b|, |g_a|, |g_b|$ and $|\tilde{\Delta}_a|, |\tilde{\Delta}_b| \gg |\Lambda_a|, |\Lambda_b|$ (for all k), whereas now Raman transitions between levels a and b should be suppressed. Hence parameters must be such that the dominant 2-photon processes are those that involve one laser photon and one cavity photon each but where the atom does no transition between levels a and b (c.f. figure 2). To avoid excitations of real photons in these processes, we thus require $\left|\Delta_a - \delta_a^k\right|, \left|\Delta_b - \delta_b^k\right| \gg \left|\frac{\Omega_a g_a}{2\Delta_a}\right|, \left|\frac{\Omega_b g_b}{2\Delta_b}\right|$ (for all k).

Whenever two atoms exchange a virtual photon in this scheme, none of them does a transition between $|a\rangle$ and $|b\rangle$. Moreover both atoms experience a Stark shift that depends on the state of the partner atom. This conditional Stark shifts play the role of an effective $\sigma^z\sigma^z$-interaction. Dropping irrelevant constants, the resulting effective Hamiltonian reads:

$$H_{\mathrm{zz}} = \sum_{j=1}^{N} \left(\tilde{B}\sigma_j^z + J_z \sigma_j^z \sigma_{j+1}^z \right) , \qquad (2)$$

where the parameters $\tilde{B}$ and J_z are given to second order by [12]. Here again, the interaction J_z and the field $\tilde{B}$ can be tuned independently, either by varying Ω_a and Ω_b for J_z or by varying Λ_a and Λ_b for $\tilde{B}$. In particular, $|\Lambda_a|^2$ and $|\Lambda_b|^2$ can for all values of Ω_a and Ω_b be chosen such that either $J_z \ll \tilde{B}$ or $J_z \gg \tilde{B}$.

The complete effective model: Making use of the Suzuki-Trotter formula, the two Hamiltonians (1) and (2) can now be combined to one effective Hamiltonian. To this end, the lasers that generate the Hamiltonian (1) are turned on for a short time interval dt $(||H_{\mathrm{xy}}|| \cdot dt \ll 1)$ followed by another time interval dt $(||H_{\mathrm{zz}}|| \cdot dt \ll 1)$ with the lasers that generate the Hamiltonian (2) turned on. This sequence is repeated until the total time range to be simulated is covered. The effective Hamiltonian simulated by this procedure is $H_{\mathrm{spin}} = H_{\mathrm{xy}} + H_{\mathrm{zz}}$ or

$$H_{\mathrm{spin}} = \sum_{j=1}^{N} \left(B_{\mathrm{tot}}\sigma_j^z + \sum_{\alpha=x,y,z} J_\alpha \sigma_j^\alpha \sigma_{j+1}^\alpha \right) , \qquad (3)$$

where $B_{\mathrm{tot}} = B + \tilde{B}$. The time interval dt should thereby be chosen such that $\Omega^{-1}, g^{-1} \ll dt_1, dt_2 \ll J_x^{-1}, J_y^{-1}, J_z^{-1}, B^{-1}$ and $\tilde{B}^{-1}$, so that the Trotter sequence concatenates the effective Hamiltonians H_{XY} and H_{ZZ}. The procedure can be generalized to higher order Trotter formulae or by turning on the sets of lasers for time intervals of different length.

Numerical tests: To confirm the validity of our approximations, we numerically simulate the dynamics generated by the full Hamiltonian H and compare it to the dynamics generated by the effective model (3).

As an example we consider two atoms in two cavities, initially in the state $\frac{1}{\sqrt{2}}(|a_1\rangle + |b_1\rangle) \otimes |a_2\rangle$, and calculate the occupation probability $p(a_1)$ of the state $|a_1\rangle$ which corresponds to the probability of spin 1 to point down, $p(\downarrow_1)$. Figure 3**a** shows $p(a_1)$ and $p(\downarrow_1)$ for an effective Hamiltonian (3) with $B_{\mathrm{tot}} = 0.135$MHz, $J_x = 0.065$MHz, $J_y = 0.007$MHz and $J_z = 0.004$MHz and hence $|B_{\mathrm{tot}}| > |J_x|$, whereas figure 3**b** shows $p(a_1)$ and $p(\downarrow_1)$ for an effective Hamiltonian (3) with $B_{\mathrm{tot}} = -0.025$MHz, $J_x = 0.065$MHz, $J_y = 0.007$MHz and $J_z = 0.004$MHz and hence $|B_{\mathrm{tot}}| < |J_x|$ [13].

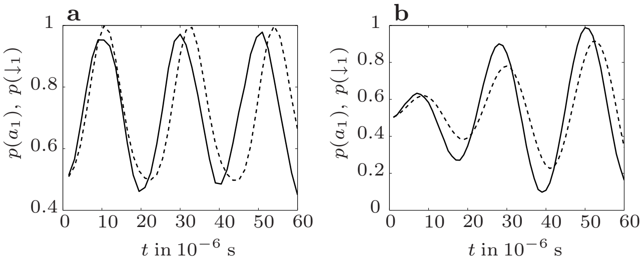

FIG. 3: The occupation probability $p(a_1)$ of state $|a_1\rangle$ (solid line) and the probability $p(\downarrow_1)$ of spin 1 to point down (dashed line) for the parameters $\omega_e = 10^6$GHz, $\omega_{ab} = 30$GHz, $\Delta_a = 30$GHz, $\Delta_b = 60$GHz, $\omega_C = \omega_e - \Delta_b + 2$GHz, $\tilde{\Delta}_a = 15$GHz, $\Omega_a = \Omega_b = 2$GHz, $\Lambda_a = \Lambda_b = 0.71$GHz, $g_a = g_b = 1$GHz, $J_C = 0.2$GHz and $\delta_1 = -0.0165$GHz (plot **a**) respectively $\delta_1 = -0.0168$GHz (plot **b**). Both, the occupation of the excited atomic states $\langle |e_j\rangle\langle e_j| \rangle$ and the photon number $\langle a^\dagger a \rangle$ are always smaller than 0.03.

Discrepancies between numerical results for the full and the effective model are due to higher order terms for the parameters [10, 12], which lead to relative corrections of up to 10% in the considered cases. Let us stress here that despite this lack of accuracy of the approximations [10, 12], the effective model is indeed a spin-1/2 Hamiltonian as occupations of excited atomic and photon states are negligible.

Cluster state generation: The Hamiltonian (2) can be used to generate cluster states [2, 14]. To this end, all atoms are initialized in the states $(|a_j\rangle + |b_j\rangle)/\sqrt{2}$, which can be done via a STIRAP process [15], and then evolved under the Hamiltonian (2) for $t = \pi/4J_z$. Figure 4 shows the von Neumann entropy of the reduced density matrix of one effective spin E_{vN} and the purity of the reduced density matrix of the effective spin chain P_{s} for a full two cavity model. Since $E_{\mathrm{vN}} \approx log_2 2$ for $t \approx 19\mu$s while the state of the effectve spin model remains highly pure

($P_{\mathrm{s}} = tr[\rho^2] > 0.95$) the degree of entanglement will be very close to maximal, see e.g. [16]. Thus the levels $|a_j\rangle$ and $|b_j\rangle$ have indeed been driven into a state which is, up to local unitary rotations, very close to a two-qubit cluster state a.k.a. singlet states.

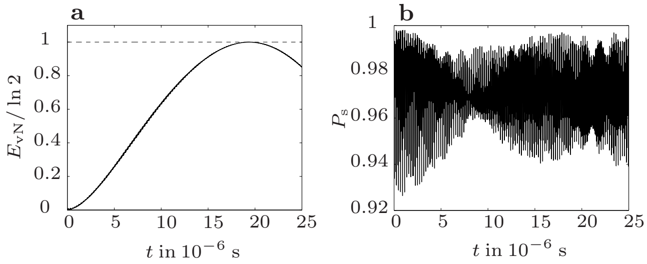

FIG. 4: **a** The von Neumann entropy E_{vN} of the reduced density matrix of 1 effective spin in multiples of $\ln 2$ and **b** the purity of the reduced state of the effective spin model for 2 cavities where $J_z = 0.042$MHz.

Experimental implementation: For an experimental implementation, the parameters of the effective Hamiltonian, J_x, J_y, J_z, B and $\tilde{B}$ have to bemuch larger than rates for decay mechanisms via the photons or the excited states $|e_j\rangle$.

With the definitions $\Omega = \max(\Omega_a, \Omega_b)$, $g = \max(g_a, g_b)$, $\Delta = \min(\Delta_a, \Delta_b)$, the occupation of the excited levels $|e_j\rangle$ can be estimated to be $\langle |e_j\rangle\langle e_j|\rangle \approx |\Omega/2\Delta|^2$, whereas the photon number is $n_p \approx |(\Omega g/2\Delta)\gamma_1|^2$ and the couplings J_x, J_y and J_z are approximately $|(\Omega g/2\Delta)|^2\gamma_2$. Spontaneous emission from the levels $|e_j\rangle$ at a rate Γ_E and cavity decay of photons at a rate Γ_C thus lead to decay rates $\Gamma_1 = |\Omega/2\Delta|^2\Gamma_E$ and $\Gamma_2 = |(\Omega g/2\Delta)\gamma_1|^2\Gamma_C$ for the effective model.

Hence, we require $\Gamma_1 \ll |(\Omega g/2\Delta)|^2\gamma_2$ and $\Gamma_2 \ll |(\Omega g/2\Delta)|^2\gamma_2$ which implies $\Gamma_E \ll J_C\, g^2/\delta^2$ and $\Gamma_C \ll J_C$ ($J_C < \delta/2$), where, $\delta = |(\omega_a + \omega_b)/2 - \omega_C|$ for the XX and YY interactions and $\delta = |\omega - \omega_C|$ for the ZZ interactions and we have approximated $|\gamma_1| \approx \delta^{-1}$ and $|\gamma_2| \approx J_C\delta^{-2}$. Since photons should be more likely to tunnel to the next cavity than decay into free space, $\Gamma_C \ll J_C$ should hold in most cases. For $\Gamma_E \ll J_C g^2/\delta^2$, to hold, cavities with a high ratio g/Γ_E are favorable. Since $\delta > 2J_C$, the two requirements together imply that the cavities should have a high cooperativity factor.

This regime can be achieved in micro-cavities, which have a small volume and thus a high g. Suitable candidates for the present proposal are for example photonic band gap cavities [5] which can either couple to atoms or quantum dots. Here, cooperativity factors of $g^2/2\Gamma_C\Gamma_E \sim 10$ and values of $g/\Gamma_E \sim 100$ have been realized and $g^2/2\Gamma_C\Gamma_E \sim 10^5$ respectively $g/\Gamma_E \sim 10^5$ are predicted to be achievable [17]. Further promising devices are micro-cavities on a gold coated silicon chip that couple to single trapped atoms, where $g^2/2\Gamma_C\Gamma_E \sim 40$ and $g/\Gamma_E \sim 50$ have been achieved [6]. Both are fabricated in large arrays and couple via the overlap of their evanescent fields or optical fibers that transfer photons from one cavity to another.

Summary: We have shown that single atoms in interacting cavities that are operated in a strong coupling regime can form a Heisenberg spin-1/2 Hamiltonian. All parameters of the effective Hamiltonian can be tuned individually, making the device a universal simulator for this model. When operated in a two dimensional array of cavities the device is thus able to simulate spin lattices which are not trackable with numerics on classical computers. Furthermore, this system can be used to generate cluster states on such lattices. Together with the possibility to measure individual lattice sites it thus provides the two key requirements for one way quantum computation. This demonstrates the versatility of the present setup for the control and manipulation of quantum systems in parameter ranges that are experimentally accessible.
